Clustering Uber Pickup Locations in NYC

Introduction

This part of the notebook applies unsupervised clustering to 20,000 Uber pickup events recorded in New York City during April 2014. The goal is to identify **geographic hotspots** — areas of consistently high pickup demand — using two complementary clustering methods: **DBSCAN** and **K-Means**.

Dataset

- Source: Uber NYC pickups (April 2014)
- Features used: `Lat` (latitude) and `Lon` (longitude)
- Sample size: 20,000 points drawn randomly from the full dataset

Methods compared

Method	Type	Key property

DBSCAN	Density-based	Finds arbitrarily shaped clusters; labels outliers as noise
K-Means	Centroid-based	Partitions all points into k spherical clusters

1. Imports & Data Loading

To balance computational efficiency and representativeness, a fixed random sample of 20,000 points is used. A fixed random seed ensures reproducibility.

In [1]:
```
from pathlib import Path

import contextily as ctx
import geopandas as gpd
import kagglehub
import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
from PIL import Image
from sklearn.cluster import DBSCAN
from sklearn.cluster import KMeans
from sklearn.metrics import (
    f1_score,
    make_scorer,
    fbeta_score,
)
from sklearn.metrics import silhouette_score, davies_bouldin_score
from sklearn.svm import SVC
from sklearn.model_selection import GridSearchCV, StratifiedKFold
```

In [2]:
```
df = pd.read_csv(
    "uber-raw-data-apr14.csv",
    usecols=["Lat", "Lon"],
    dtype={"Lat": "float32", "Lon": "float32"}
).dropna()

print(df.shape)
```

```
(564516, 2)
```

In [3]:
```
df = df.sample(n=20000, random_state=0)
```

2. Exploratory Data Analysis

Before clustering, we visualise the raw pickup distribution. Darker, denser regions are natural candidates for cluster centres — and already hint at major hubs like Midtown, JFK, and LaGuardia.

In [4]:
```
gdf = gpd.GeoDataFrame(
    df,
    geometry=gpd.points_from_xy(df["Lon"], df["Lat"]),
    crs="EPSG:4326"  # lat/lon
)
```

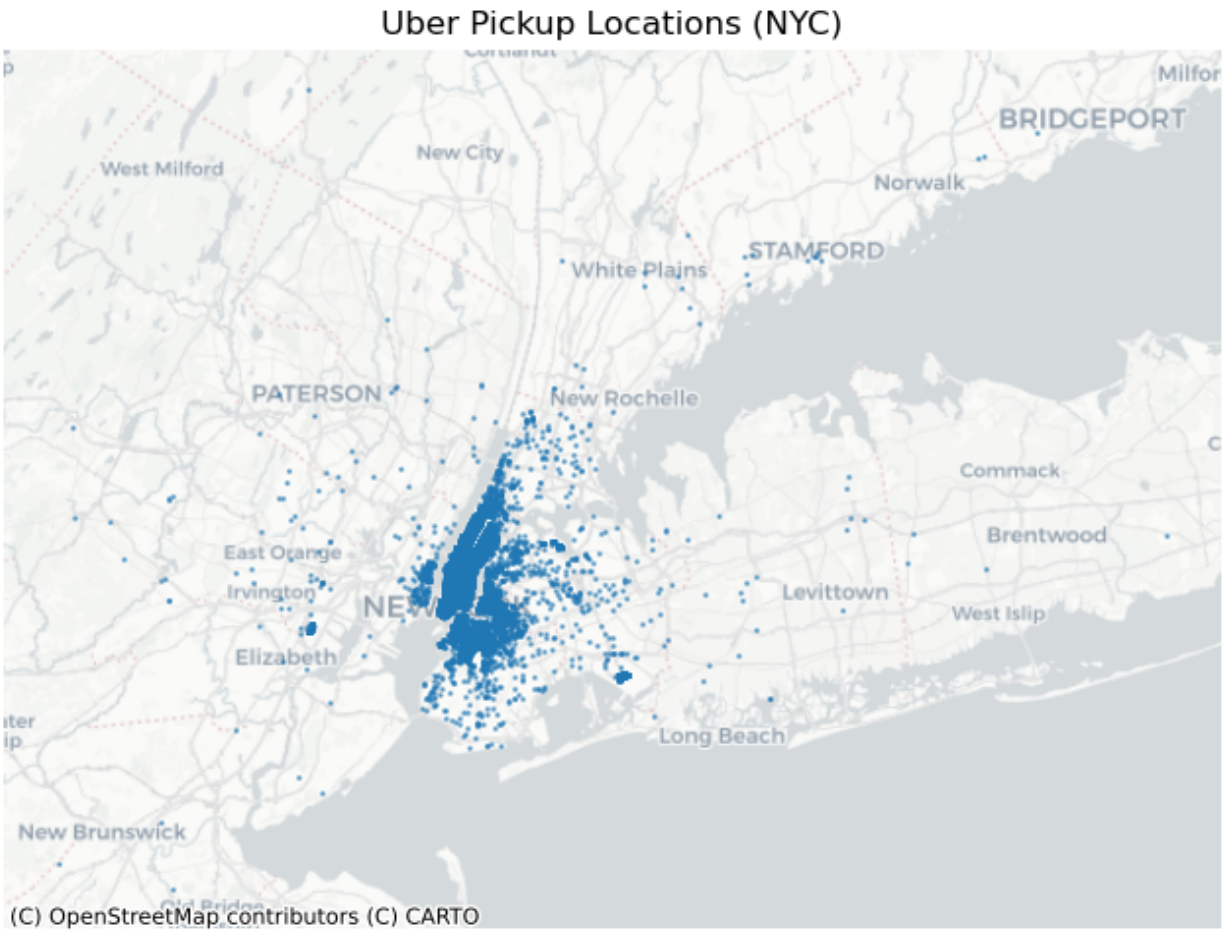
```
gdf = gdf.to_crs(epsg=3857)

fig, ax = plt.subplots(figsize=(8, 8))

# Plot clusters
gdf.plot(
    ax=ax,
    markersize=1,
    alpha=0.5
)
# Add map
ctx.add_basemap(ax, source=ctx.providers.CartoDB.Positron)

ax.set_title("Uber Pickup Locations (NYC)")
ax.set_axis_off()  # cleaner look

plt.show()
```



3. Coordinate Preprocessing

Coordinates are converted to radians for DBSCAN, which uses the haversine metric to compute great-circle distances.

K-Means, however, operates in Euclidean space and is applied directly to latitude and longitude coordinates. While this introduces slight distortion, it is acceptable for a geographically limited region like NYC.

In [5]:
```
coords_deg = df[['Lat', 'Lon']].to_numpy()
coords_rad = np.radians(coords_deg)
```

4. DBSCAN Clustering

Algorithm overview

DBSCAN (Density-Based Spatial Clustering of Applications with Noise) groups points within a dense neighbourhood, labelling sparse outliers as **noise** (label = −1). It has two parameters:

Parameter	Role
`eps`	Neighbourhood radius — maximum haversine distance between two neighbours
`min_samples`	Minimum neighbours required for a point to be a *core point*

Why DBSCAN suits geographic data: it does not assume circular clusters, naturally identifies outliers, and does not require a pre-specified cluster count.

4.1 Parameter Tuning

We tune `eps` and `min_samples` sequentially, fixing one while sweeping the other. For each combination we track two statistics:

- **Number of clusters** — should be geographically interpretable (not hundreds of micro-clusters, not just 2–3 mega-regions)
- **Noise %** — should be low enough that we're not discarding real pickups, but not forced to zero

Step 1 — Sweep `eps` (min_samples=10 fixed)

In [6]:
```
eps_values = np.arange(0.05, 0.51, 0.05)
kms_per_radian = 6371.0088
n_clusters_list = []
noise_pct_list = []

for eps_km in eps_values:
    epsilon = eps_km / kms_per_radian
    db = DBSCAN(eps=epsilon, min_samples=10, metric='haversine')
    labels = db.fit_predict(coords_rad)
    n_clusters = len(set(labels)) - (1 if -1 in labels else 0)
    noise_pct = (labels == -1).mean() * 100
    n_clusters_list.append(n_clusters)
    noise_pct_list.append(noise_pct)

fig, ax1 = plt.subplots(figsize=(12, 5))

color1 = 'steelblue'
ax1.set_xlabel('eps (km)')
```

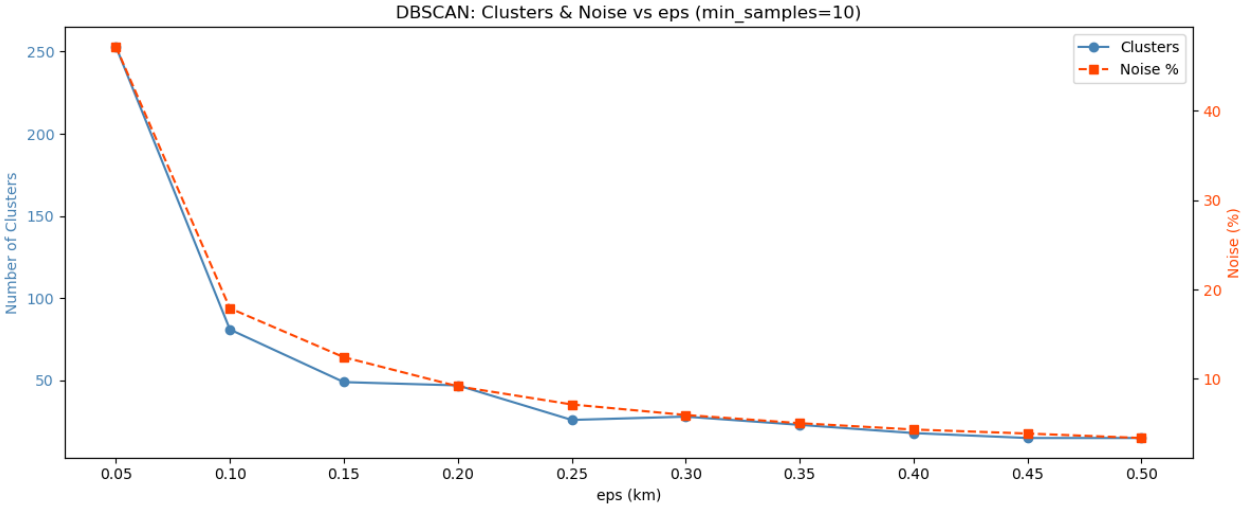
```
ax1.set_ylabel('Number of Clusters', color=color1)
ax1.plot(eps_values, n_clusters_list, marker='o', color=color1, label='Cl
ax1.tick_params(axis='y', labelcolor=color1)

ax2 = ax1.twinx()
color2 = 'orangered'
ax2.set_ylabel('Noise (%)', color=color2)
ax2.plot(eps_values, noise_pct_list, marker='s', linestyle='--', color=co
ax2.tick_params(axis='y', labelcolor=color2)

lines1, labels1 = ax1.get_legend_handles_labels()
lines2, labels2 = ax2.get_legend_handles_labels()
ax1.legend(lines1 + lines2, labels1 + labels2, loc='upper right')

plt.title('DBSCAN: Clusters & Noise vs eps (min_samples=10)')
ax1.set_xticks(eps_values)
ax1.set_xticklabels([f'{e:.2f}' for e in eps_values])
plt.tight_layout()
plt.show()

idx = np.argmin(np.abs(eps_values - 0.3))
print(f"eps=0.3km → {n_clusters_list[idx]} clusters, {noise_pct_list[idx]
```



```
eps=0.3km → 28 clusters, 6.0% noise
```

- **eps = 0.05 – 0.10**: The number of clusters drops sharply, while the noise percentage also decreases significantly. This indicates that at very small eps values, the data is highly fragmented into many small, spurious clusters (over-fragmentation). Increasing eps in this range helps merge nearby points into more meaningful clusters and reduces noise.

- **eps = 0.10 – 0.30**: The number of clusters continues to decrease, but at a slower rate, with some fluctuations. The noise percentage also keeps decreasing but more gradually. This suggests a transition phase where clusters are being consolidated into more stable and meaningful structures. The fluctuations indicate sensitivity to local density variations.

- **eps ≥ 0.30**: The number of clusters stabilizes and only decreases slightly, while the noise percentage shows minimal improvement. This reflects a plateau region

with diminishing returns, where increasing eps no longer significantly improves clustering quality but may lead to oversmoothing by merging distinct clusters.

Selected: `eps = 0.3 km`, giving 28 clusters at 6% noise.

Step 2 — Sweep `min_samples` (eps=0.3 km fixed)

In [7]:
```
ms_values = range(3, 26)
n_clusters_list = []
noise_pct_list = []

for ms in ms_values:
    db = DBSCAN(eps=0.3 / 6371, min_samples=ms, metric='haversine')
    labels = db.fit_predict(coords_rad)
    n_clusters = len(set(labels)) - (1 if -1 in labels else 0)
    noise_pct = (labels == -1).mean() * 100
    n_clusters_list.append(n_clusters)
    noise_pct_list.append(noise_pct)

fig, ax1 = plt.subplots(figsize=(12, 5))

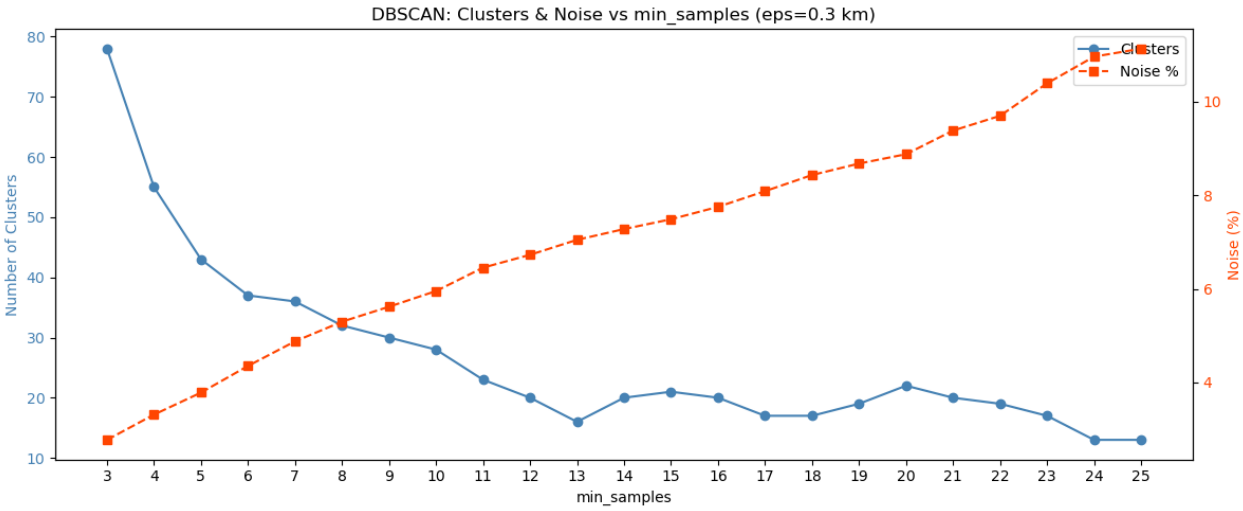
# left axis: clusters
color1 = 'steelblue'
ax1.set_xlabel('min_samples')
ax1.set_ylabel('Number of Clusters', color=color1)
ax1.plot(ms_values, n_clusters_list, marker='o', color=color1, label='Clu
ax1.tick_params(axis='y', labelcolor=color1)

# right axis: noise
ax2 = ax1.twinx()
color2 = 'orangered'
ax2.set_ylabel('Noise (%)', color=color2)
ax2.plot(ms_values, noise_pct_list, marker='s', linestyle='--', color=col
ax2.tick_params(axis='y', labelcolor=color2)

lines1, labels1 = ax1.get_legend_handles_labels()
lines2, labels2 = ax2.get_legend_handles_labels()
ax1.legend(lines1 + lines2, labels1 + labels2, loc='upper right')

plt.title('DBSCAN: Clusters & Noise vs min_samples (eps=0.3 km)')
plt.xticks(ms_values)
plt.tight_layout()
plt.show()

idx = list(ms_values).index(5)
print(f"min_samples = 5 → {n_clusters_list[idx]} clusters, {noise_pct_lis
```



```
min_samples = 5 → 43 clusters, 3.8% noise
```

- **min_samples = 3 - 5**: the number of clusters decreases sharply, while noise increases only slightly. This indicates that many spurious micro-clusters are being removed, improving clustering quality without significant information loss.
- **min_samples = 5 - 13**: Between min_samples = 5 and 13, the number of clusters continues to decrease, but at a slower rate. This suggests that the algorithm is no longer removing only noise, but also beginning to merge or eliminate smaller meaningful clusters, indicating a transition phase.
- **min_samples > 13**: Beyond min_samples = 13, the number of clusters fluctuates slightly and no longer shows a clear downward trend, while the noise percentage continues to increase steadily. This indicates a plateau region with diminishing returns, where increasing min_samples does not meaningfully improve the clustering structure but instead discards more valid data points as noise.

Selected: `min_samples = 5`, giving 43 clusters at 3.8% noise.

In [8]:
```
def plot_dbscan(ax, coords_rad, df, eps_km, min_samples):
    eps = eps_km / kms_per_radian

    db = DBSCAN(
        eps=eps,
        min_samples=min_samples,
        metric='haversine',
        algorithm='ball_tree'
    )
    labels = db.fit_predict(coords_rad)

    noise = labels == -1
    clusters = labels != -1

    ax.scatter(df['Lon'][noise], df['Lat'][noise], s=1, c='lightgray', la
    ax.scatter(df['Lon'][clusters], df['Lat'][clusters], s=2, c=labels[cl

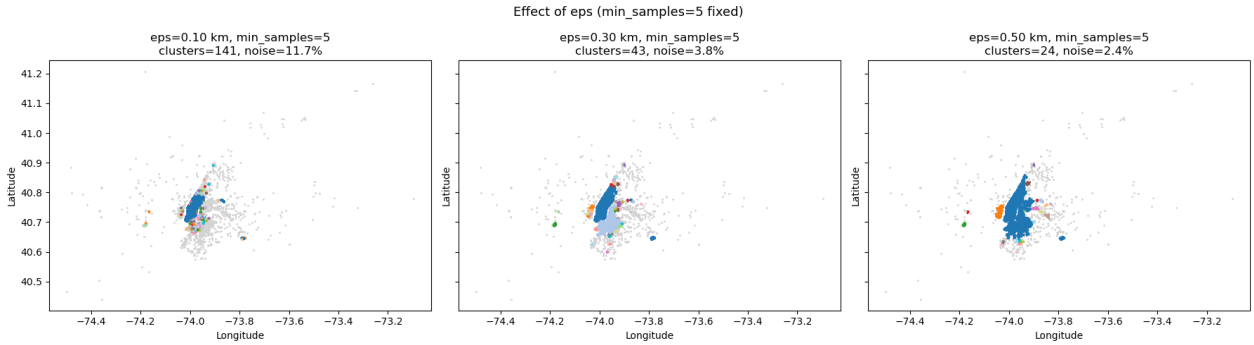
    n_clusters = len(set(labels)) - (1 if -1 in labels else 0)
    noise_ratio = noise.mean()
```

```
    ax.set_title(f"eps={eps_km:.2f} km, min_samples={min_samples}\ncluste
    ax.set_xlabel("Longitude")
    ax.set_ylabel("Latitude")
```

In [9]:
```
# Varying eps with min_samples=5 fixed
fig, axes = plt.subplots(1, 3, figsize=(18, 5), sharex=True, sharey=True)

for ax, eps_km in zip(axes, [0.1, 0.3, 0.5]):
    plot_dbscan(ax, coords_rad, df, eps_km=eps_km, min_samples=5)

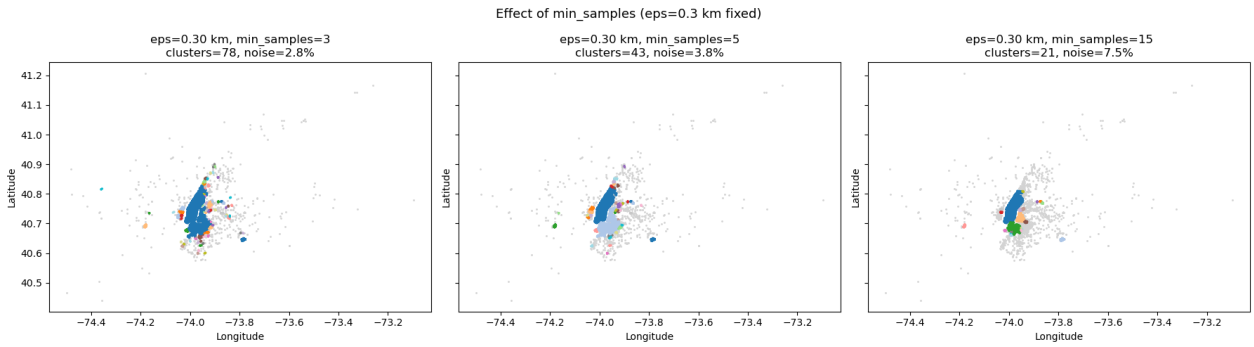
fig.suptitle("Effect of eps (min_samples=5 fixed)", fontsize=13)
plt.tight_layout()
plt.show()
```



In [10]:
```
# Varying min_samples with eps=0.3 km fixed
fig, axes = plt.subplots(1, 3, figsize=(18, 5), sharex=True, sharey=True)

for ax, ms in zip(axes, [3, 5, 15]):
    plot_dbscan(ax, coords_rad, df, eps_km=0.3, min_samples=ms)

fig.suptitle("Effect of min_samples (eps=0.3 km fixed)", fontsize=13)
plt.tight_layout()
plt.show()
```



The parameter tuning results show that DBSCAN is highly sensitive to both the distance threshold (eps) and the minimum number of points required to form a cluster (min_samples).

Increasing eps leads to larger clusters and fewer noise points, as more points fall within the neighborhood radius and become connected. However, if eps is too large, distinct regions merge into a single cluster.

Increasing min_samples makes the clustering more conservative by requiring higher density to form clusters. This reduces the number of clusters but increases the

number of points labeled as noise.

A balance between these parameters is necessary to obtain meaningful clusters. In this analysis, eps = 0.3 km and min_samples = 5 provide a reasonable trade-off between cluster detail and stability.

4.3 Final DBSCAN Result

Chosen parameters: `eps = 0.3 km`, `min_samples = 5`

This choice balances fragmentation (too small eps) and over-merging (too large eps), while maintaining a reasonable level of noise.

In [11]:
```
db = DBSCAN(eps=0.3 / 6371, min_samples=5, metric='haversine')

db.fit(coords_rad)
y_pred = db.labels_
```

In [12]:
```
# ------------------------
# 1) Create GeoDataFrame
# ------------------------
gdf = gpd.GeoDataFrame(
    df,
    geometry=gpd.points_from_xy(df["Lon"], df["Lat"]),
    crs="EPSG:4326"
)

# Project to Web Mercator
gdf = gdf.to_crs(epsg=3857)

# Keep cluster labels aligned
gdf["cluster"] = y_pred

# ------------------------
# 2) Separate noise
# ------------------------
noise = gdf["cluster"] == -1

# ------------------------
# 3) Plot
# ------------------------
fig, ax = plt.subplots(figsize=(6, 6))

# Plot noise
gdf[noise].plot(
    ax=ax,
    markersize=1,
    color="lightgray",
    label="Noise",
    alpha=0.5
)

# Plot clusters
gdf[~noise].plot(
```

```
    ax=ax,
    column="cluster",
    cmap="tab20",
    markersize=2,
    alpha=0.8
)

# ------------------------
# 4) Zoom In a bit (use total_bounds in projected coords)
# ------------------------
x_min, y_min, x_max, y_max = gdf.total_bounds

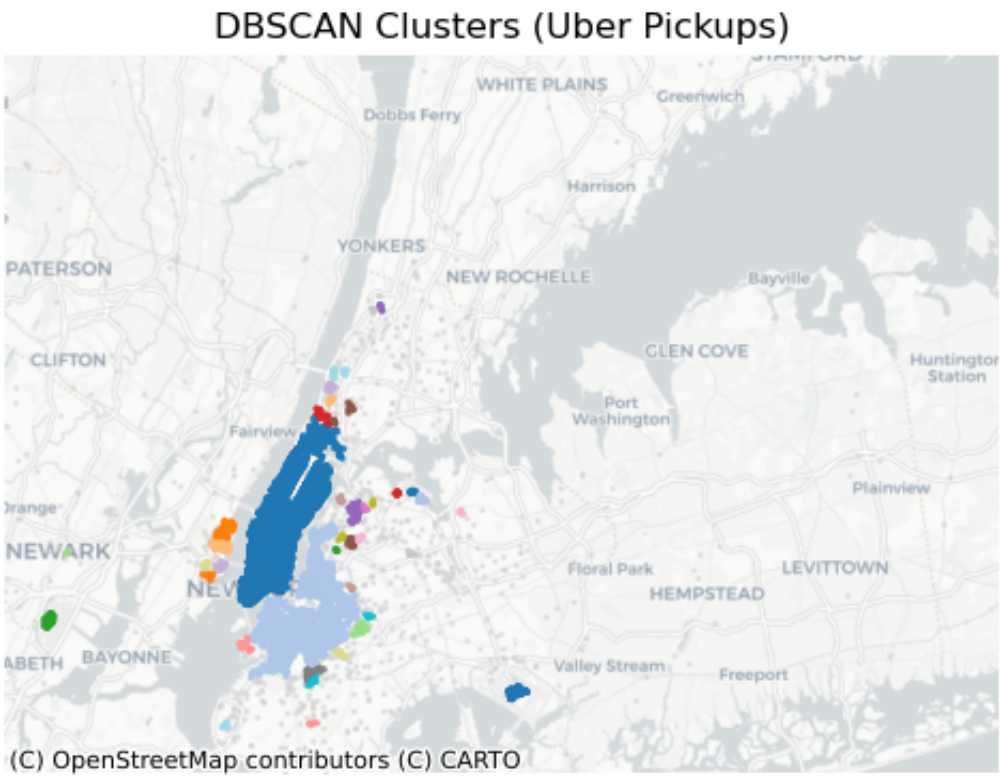
# Optional tighter zoom
pad_x = (x_max - x_min) * 0.2
pad_y = (y_max - y_min) * 0.2

ax.set_xlim(x_min + pad_x, x_max - pad_x)
ax.set_ylim(y_min + pad_y, y_max - pad_y)

# ------------------------
# 5) Add basemap
# ------------------------
ctx.add_basemap(ax, source=ctx.providers.CartoDB.Positron)

# ------------------------
# 6) Final styling
# ------------------------
ax.set_title("DBSCAN Clusters (Uber Pickups)")
ax.set_axis_off()  # cleaner for maps

plt.show()
```



The DBSCAN clustering reveals a dominant high-density cluster covering most of Manhattan, indicating that pickup locations in this area are highly connected within

the chosen distance threshold. In contrast, surrounding regions such as Brooklyn, Queens, and New Jersey form smaller, localized clusters, reflecting lower density and more fragmented spatial patterns.

This result highlights the strong concentration of Uber activity in Manhattan and demonstrates how DBSCAN groups spatially continuous high-density areas into a single cluster. The clustering outcome is sensitive to the choice of the distance parameter (eps), which determines the scale at which clusters are identified.

5. K-Means Clustering

Algorithm overview

K-Means partitions all points into exactly **k clusters** by iteratively minimising the within-cluster sum of squared distances to each centroid. Every point is assigned to a cluster — there are no noise points.

Limitations for geographic data:

- Assumes clusters are roughly **spherical and equal-sized**
- Sensitive to the choice of k
- Cannot identify outliers — isolated pickups are forced into the nearest cluster

5.1 Choosing Optimal k

We use two complementary diagnostics on the full 20,000-point dataset:

- **Elbow method** — inertia vs k; look for where improvement slows
- **Silhouette score** — cluster separation quality (range −1 to 1, higher is better)

In [13]:
```
inertias, silhouettes = [], []
for k in range(2, 15):
    km = KMeans(n_clusters=k, random_state=0)
    labels = km.fit_predict(coords_deg)
    inertias.append(km.inertia_)
    silhouettes.append(silhouette_score(coords_deg, labels, sample_size=5

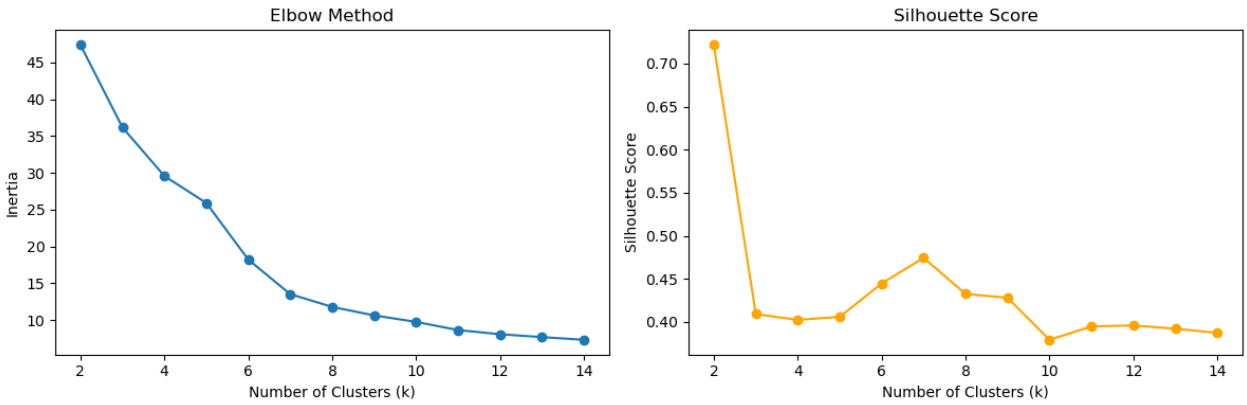
fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(12, 4))

ax1.plot(range(2, 15), inertias, marker='o')
ax1.set_title("Elbow Method")
ax1.set_xlabel("Number of Clusters (k)")
ax1.set_ylabel("Inertia")

ax2.plot(range(2, 15), silhouettes, marker='o', color='orange')
ax2.set_title("Silhouette Score")
ax2.set_xlabel("Number of Clusters (k)")
ax2.set_ylabel("Silhouette Score")

plt.tight_layout()
```

```
plt.show()
```



Findings:

- The elbow curve starts to flatten after k = 7, indicating diminishing returns in reducing inertia.
- The silhouette peaks at **k=2**, but two clusters simply splits NYC in half — geographically meaningless. This is a known limitation of silhouette: it can favour trivially coarse solutions. The **next local peak at k=7** aligns with recognisable NYC zones: Midtown, Lower Manhattan, Upper Manhattan, JFK, LaGuardia, Brooklyn, and the outer boroughs. The elbow plot shows no sharp kink, which is typical for continuous geographic distributions. **Selected:** `k = 7`.

5.2 Final K-Means Result

Chosen parameters: `n_clusters = 7`

In [14]:
```
kmeans = KMeans(n_clusters=7, random_state=0)
kmeans.fit(coords_deg)
k_labels = kmeans.labels_

# 1) Save labels into dataframe
df["kmeans_7"] = k_labels

# 2) Create GeoDataFrame (lat/lon)
gdf = gpd.GeoDataFrame(
    df,
    geometry=gpd.points_from_xy(df["Lon"], df["Lat"]),
    crs="EPSG:4326"
)

# 3) Project to Web Mercator (required for basemap)
gdf = gdf.to_crs(epsg=3857)

# 4) Plot
fig, ax = plt.subplots(figsize=(6, 6))

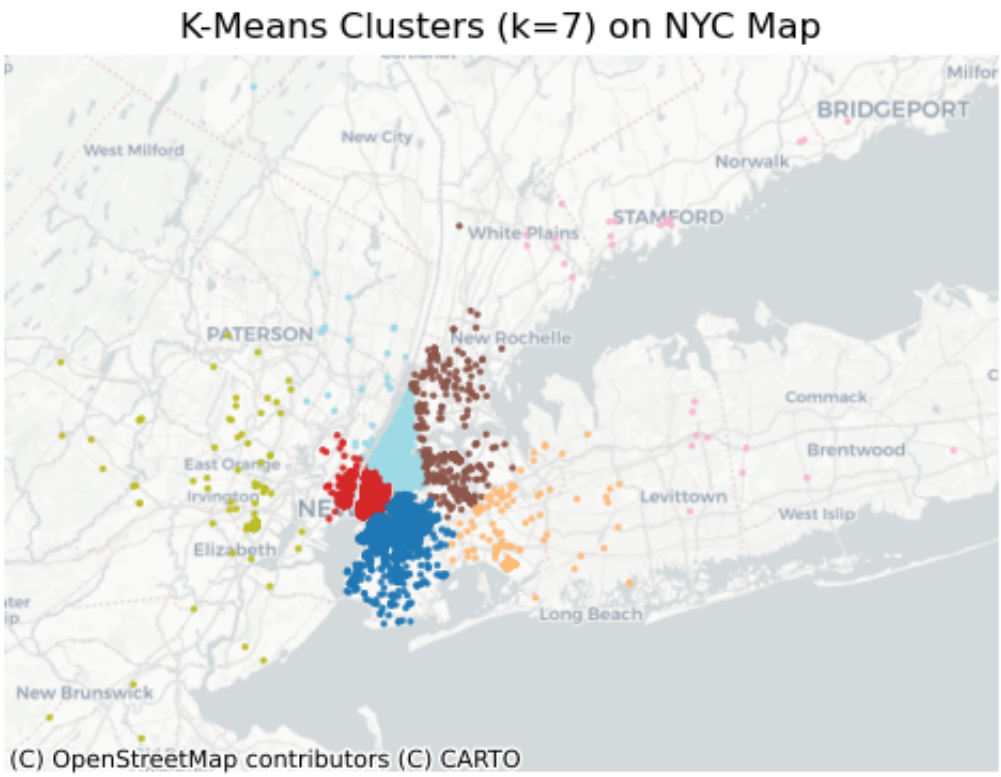
gdf.plot(
    ax=ax,
    column="kmeans_7",
    cmap="tab20",
```

```
    markersize=2,
    alpha=0.8
)

# 5) Add basemap
ctx.add_basemap(ax, source=ctx.providers.CartoDB.Positron)

ax.set_title("K-Means Clusters (k=7) on NYC Map")
ax.set_axis_off()

plt.show()
```



The K-Means clustering (k=7) partitions NYC into seven spatial regions based on proximity to cluster centroids. Dense areas such as Manhattan are divided into multiple clusters, while less dense outer regions form broader clusters. The geometric shapes of the clusters reflect the distance-based nature of K-Means, rather than underlying spatial density patterns.

Unlike DBSCAN, which identifies natural clusters and noise, K-Means assigns every point to a cluster, resulting in a complete partition of the space. This highlights the difference between segmentation (K-Means) and density-based clustering (DBSCAN).

6. Quantitative Evaluation

Metrics

Since we have no ground-truth zone labels, we use **unsupervised** metrics only:

Metric	Direction	What it measures

Silhouette Score	↑ higher is better	How well-separated each point is from neighbouring clusters
Davies-Bouldin Index	↓ lower is better	Average similarity between each cluster and its closest neighbour

Note: DBSCAN noise points (label = –1) are excluded before computing metrics, so evaluation covers the 96.2% of points that were assigned to a cluster.

In [15]:
```
# KMeans
print("KMeans Silhouette:", silhouette_score(coords_deg, k_labels))
print("KMeans Davies-Bouldin:", davies_bouldin_score(coords_deg, k_labels

# DBSCAN - must exclude noise points
mask = y_pred != -1
print("DBSCAN Silhouette:", silhouette_score(coords_rad[mask], y_pred[mas
print("DBSCAN Davies-Bouldin:", davies_bouldin_score(coords_rad[mask], y_
```

```
KMeans Silhouette: 0.475241
KMeans Davies-Bouldin: 0.6357683501421347
DBSCAN Silhouette: 0.13807006
DBSCAN Davies-Bouldin: 0.4904070838180985
```

Interpreting the metrics

The metrics do not point to a single “winner” because they evaluate different properties of clustering.

Silhouette Score (K-Means higher): Measures how well each point fits within its cluster compared to other clusters (ranges from -1 to 1; higher is better). It rewards compact and well-separated clusters. K-Means scores higher because it is explicitly optimized for compact, spherical clusters. DBSCAN’s irregular, elongated clusters naturally lead to lower silhouette scores, even when they reflect real spatial structure.

Davies-Bouldin Index (DBSCAN lower): Measures the average similarity between clusters based on their compactness and separation (lower is better). It penalizes clusters that are close together or overlapping. DBSCAN performs better because it identifies spatially distinct hotspots, while K-Means partitions space into adjacent regions with less clear boundaries.

7. Conclusion

DBSCAN is better suited for identifying meaningful pickup patterns. Uber pickups are highly concentrated and follow irregular spatial structures (e.g., street networks and activity hubs). DBSCAN captures these patterns naturally without imposing geometric assumptions, and its ability to label noise provides additional insight into sparse or isolated events.

K-Means, however, remains useful for spatial segmentation. When the goal is to

divide the city into a fixed number of zones (e.g., for routing or demand forecasting), K-Means provides a complete and interpretable partition, even if the boundaries are artificial.

K-Means answers “how to divide the space,” while DBSCAN answers “where activity is concentrated.”

Overall, this comparison highlights that clustering results are not absolute, but depend on the algorithm’s assumptions, parameter choices, and the spatial scale of the data.

Limitations

- DBSCAN metrics exclude noise points, making the silhouette comparison slightly asymmetric
- Both models are evaluated on a 20,000-point sample; results may vary on the full dataset
- Automated metrics (e.g., silhouette favoring k=2) can suggest trivial solutions, highlighting the importance of domain knowledge

Support Vector Machines — Machine Learning Assignment 2, Part 2

Overview

In this part, we develop a Support Vector Machine (SVM) to classify medical images related to COVID-19. The primary objective is to evaluate how different SVM configurations influence classification performance, with a particular focus on balancing overall accuracy and recall in a medical diagnostic context.

The dataset consists of labeled medical images, which are preprocessed into grayscale and flattened into one-dimensional feature vectors suitable for SVM models.

Key Design Choices

1. Fixed train/test split to ensure a fair comparison across all projected dimensions.
2. Images are resized and converted to grayscale, then flattened into feature vectors to match the input requirements of SVM models.
3. Hyperparameter optimization is performed using GridSearchCV with Stratified K-Fold cross-validation to systematically explore different kernel configurations.
4. Multiple SVM kernels (RBF and Polynomial) are compared to analyze their impact on model generalization.
5. A sensitivity analysis is conducted on the polynomial degree to study overfitting and underfitting behavior.

6. Performance is evaluated using appropriate metrics, with particular attention to recall-oriented measures relevant for medical diagnosis.
7. Final models are selected and evaluated based on different optimization objectives to provide a comprehensive performance assessment.

Dataset Choice

We are using a Dataset of Covid-19 thorax scans where we classify if a certain scan has either Covid-19, Nothing or Viral Pneumonia. The Dataset contains 317 scans overall and 251 of those are training files and 66 test files All the scans have different resolutions, so we standardize it to 128 x 128 pixels in Grayscale since color is not needed in Covid-19 diagnosis

Data Exploration: Class Visualization

Prior to model training, it is crucial to visually inspect representative samples from each target class. As the Support Vector Machine (SVM) pipeline requires one-dimensional feature vectors, the images have been preprocessed into flattened grayscale arrays. The following cell reconstructs these arrays into two-dimensional matrices to verify the integrity of the data transformations and establish a baseline understanding of the distinct pathological features.

In [21]:

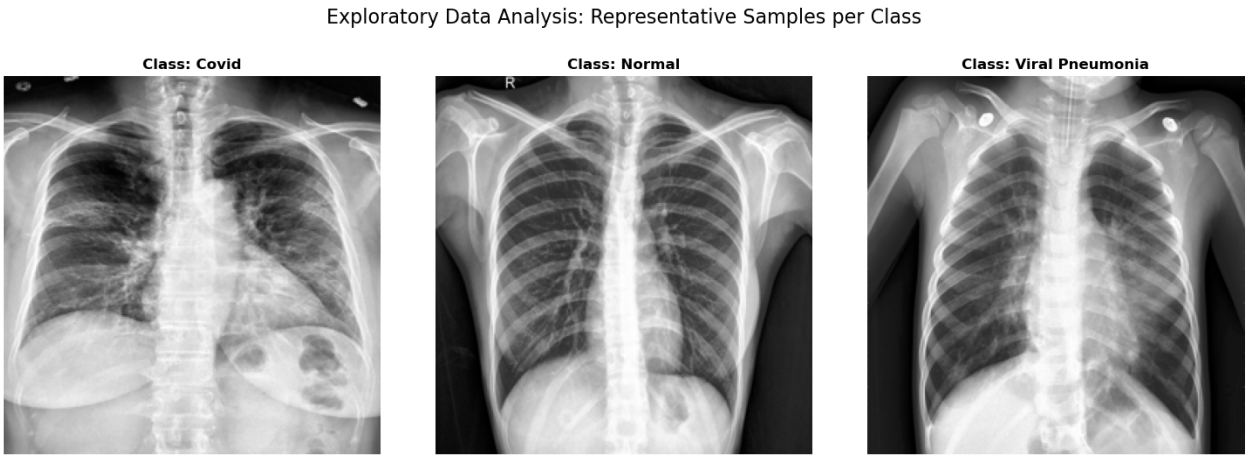
```
# Define visualization parameters
fig, axes = plt.subplots(1, 3, figsize=(15, 5))

for i, cls_name in enumerate(classes):
    # Locate the first instance of the class in the training set
    idx = np.where(y_train == class_to_idx[cls_name])[0][0]

    # Robust Reshaping: Detects if data is RGB or Grayscale
    if not GRAYSCALE:
        # Reshape to (H, W, Channels) for RGB
        img_arr = X_train[idx].reshape((*IMAGE_SIZE, 3))
    else:
        # Reshape to (H, W) for Grayscale
        img_arr = X_train[idx].reshape(IMAGE_SIZE)

    # Render with appropriate colormap
    axes[i].imshow(img_arr, cmap='gray' if GRAYSCALE else None)
    axes[i].set_title(f"Class: {cls_name}", fontweight='bold')
    axes[i].axis('off')

plt.suptitle("Exploratory Data Analysis: Representative Samples per Class
plt.tight_layout()
plt.show()
```



Hyperparameter Optimization & Model Selection (NEW)

In this stage, we employ a **Grid Search with Cross-Validation (GridSearchCV)** to systematically evaluate the performance of different Support Vector Machine (SVM) kernels. We optimize for two distinct clinical objectives based on the fundamental metrics of precision and recall:

$$\text{Precision} = \frac{TP}{TP + FP}$$

$$\text{Recall} = \frac{TP}{TP + FN}$$

The general F_β score mathematically relates these two metrics, weighted by a factor of β:

$$F_\beta = (1 + \beta^2) \cdot \frac{\text{Precision} \cdot \text{Recall}}{(\beta^2 \cdot \text{Precision}) + \text{Recall}}$$

1. **F1-Macro:** Setting $\beta = 1$ provides a balanced measure of precision and recall, suitable for general diagnostic accuracy.
2. **F2-Macro:** Setting $\beta = 2$ places twice the weight on **Recall**, which is critical in medical screening to minimize "False Negatives" (missing a positive COVID-19 case).

> **Note:** We specifically track both training and validation scores to perform a **Sensitivity Analysis** of model complexity.

In [22]:
```
scoring = {
    'f1_macro': 'f1_macro',
    'f2_macro': make_scorer(fbeta_score, beta=2, average='macro')
}
```

Hyperparameter Optimization via Grid Search

Support Vector Machine performance is heavily dependent on the optimal selection of hyperparameters. To systematically identify the highest-performing configuration and mitigate the risk of overfitting, we employ an exhaustive `GridSearchCV` over a predefined parameter space using Stratified K-Fold cross-validation. This search evaluates two primary kernel functions:

- **Radial Basis Function (RBF):** Effective for modeling complex, non-linear decision boundaries. We optimize the regularization parameter (`C`) and the kernel coefficient (`gamma`).
- **Polynomial:** Projects the feature space into higher dimensions using polynomial transformations. We tune the polynomial `degree`, alongside `C`, `gamma`, and the independent term (`coef0`).

In [23]:
```
param_grid = [
    {
        "kernel": ["rbf"],
        "C": [0.1, 1, 10, 100],
        "gamma": ["scale", 1e-3, 1e-4],
        "class_weight": [None, "balanced"],
    },
    {
        "kernel": ["poly"],
        "C": [0.1, 1, 10, 100],
        "degree": [2, 3, 4, 5, 6, 7, 8],
        "gamma": ["scale", 1e-3],
        "coef0": [0.0, 1.0],
        "class_weight": [None, "balanced"],
    },
]
```

In [24]:
```
cv = StratifiedKFold(n_splits=5, shuffle=True, random_state=42)

# Execute GridSearchCV with multiple scoring metrics
# Note: refit is set to False to allow manual extraction of multiple 'bes
grid = GridSearchCV(
    estimator=SVC(),
    param_grid=param_grid,
    scoring=scoring,
    refit=False,  # We will manually refit for both F1 and F2
    cv=cv,
    n_jobs=-1,
    verbose=1,
    return_train_score=True
)

grid.fit(X_train, y_train)
```

```
Fitting 5 folds for each of 248 candidates, totalling 1240 fits
```

Out[24]:

```
▸ GridSearchCV
▸ estimator: SVC
  ▸ SVC
```

These 1240 fits took 14 minutes on a AMD Ryzen 7 5800X3D 8-Core 16-Thread Processor with 32GB of 3200MHz Ram

5. Sensitivity Analysis: Polynomial Degree vs. Generalization

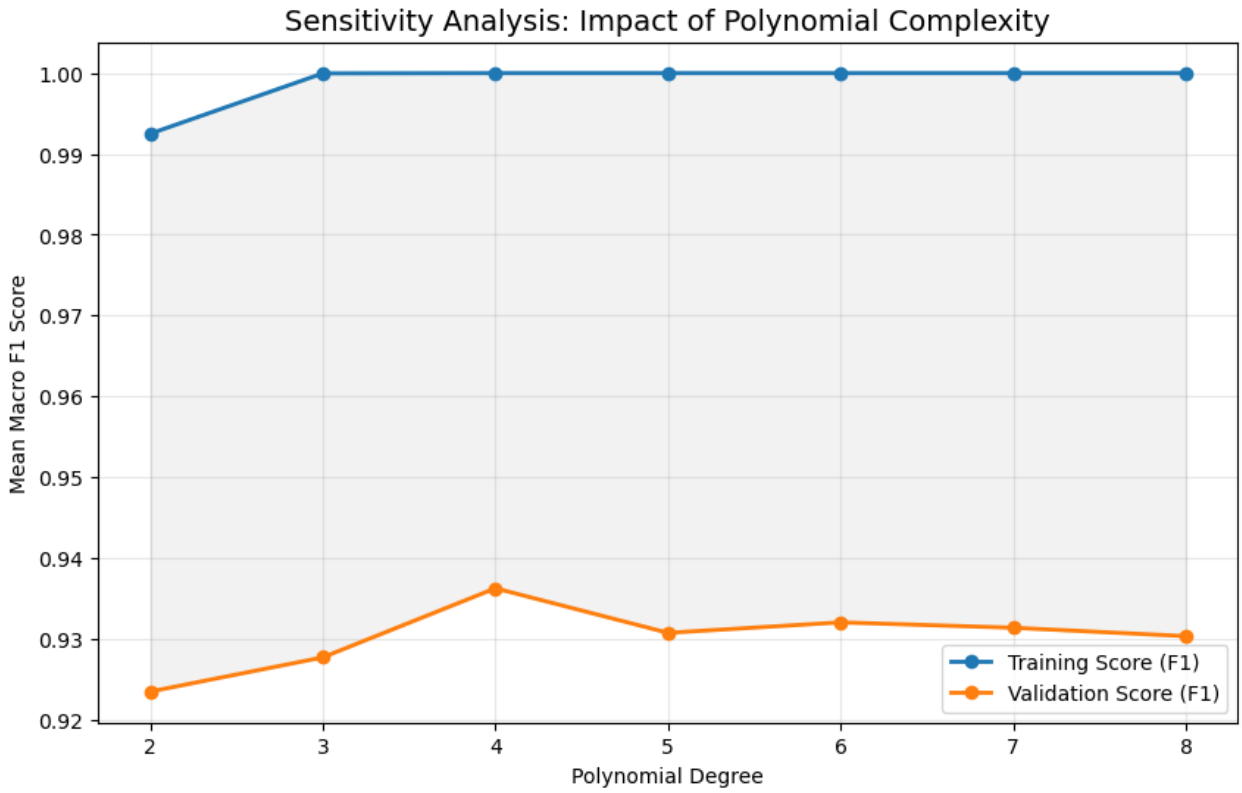
The following analysis evaluates the **Sensitivity** of the Polynomial kernel to its `degree` parameter. By plotting both Training and Validation scores, we can identify the "Generalization Gap." A widening gap indicates **Overfitting** (High Variance), while low scores on both indicate **Underfitting** (High Bias).

In [28]:

```
# Extract and filter results for the Polynomial kernel
results_df = pd.DataFrame(grid.cv_results_)
poly_sens = results_df[results_df['param_kernel'] == 'poly'].copy()
poly_sens['param_degree'] = poly_sens['param_degree'].astype(int)
poly_sens = poly_sens.groupby('param_degree')[['mean_train_f1_macro', 'me

plt.figure(figsize=(10, 6))
plt.plot(poly_sens['param_degree'], poly_sens['mean_train_f1_macro'], lab
         linewidth=2)
plt.plot(poly_sens['param_degree'], poly_sens['mean_test_f1_macro'], labe
         linewidth=2)
plt.fill_between(poly_sens['param_degree'], poly_sens['mean_test_f1_macro
                 alpha=0.1, color='gray')

plt.title('Sensitivity Analysis: Impact of Polynomial Complexity', fontsi
plt.xlabel('Polynomial Degree')
plt.ylabel('Mean Macro F1 Score')
plt.grid(True, alpha=0.3)
plt.legend()
plt.show()
```



Analysis of Polynomial Complexity Graph

Any polynomial degree over 2 is completely overfitting in the training step, most likely due to lower pixel resolution and the low amount of training data; fortunately, we do see an increase in validation Score going up the degrees at some point which means that higher degrees do generalize better, at least up to degree 5

In [29]:

```
import seaborn as sns
import matplotlib.pyplot as plt

def get_fold_distributions(grid_search, kernels=['rbf', 'poly'], metric='
    """
    Extracts individual fold scores for the top-performing configuration
    """
    results = pd.DataFrame(grid_search.cv_results_)
    # Access the number of splits used during the grid search
    n_splits = grid_search.n_splits_

    fold_data = []
    for kernel in kernels:
        # Isolate results for the specific kernel architecture
        subset = results[results['param_kernel'] == kernel]
        if subset.empty:
            continue

        # Identify the index of the highest mean score for the chosen met
        best_idx = subset[f'mean_test_{metric}'].idxmax()

        # Collect scores from each split (e.g., split0_test_f1_macro, spl
        for fold in range(n_splits):
            score = subset.loc[best_idx, f'split{fold}_test_{metric}']
```

```
            fold_data.append({
                'Kernel': kernel.upper(),
                'Metric Score': score,
                'Fold': f'Fold {fold + 1}'
            })

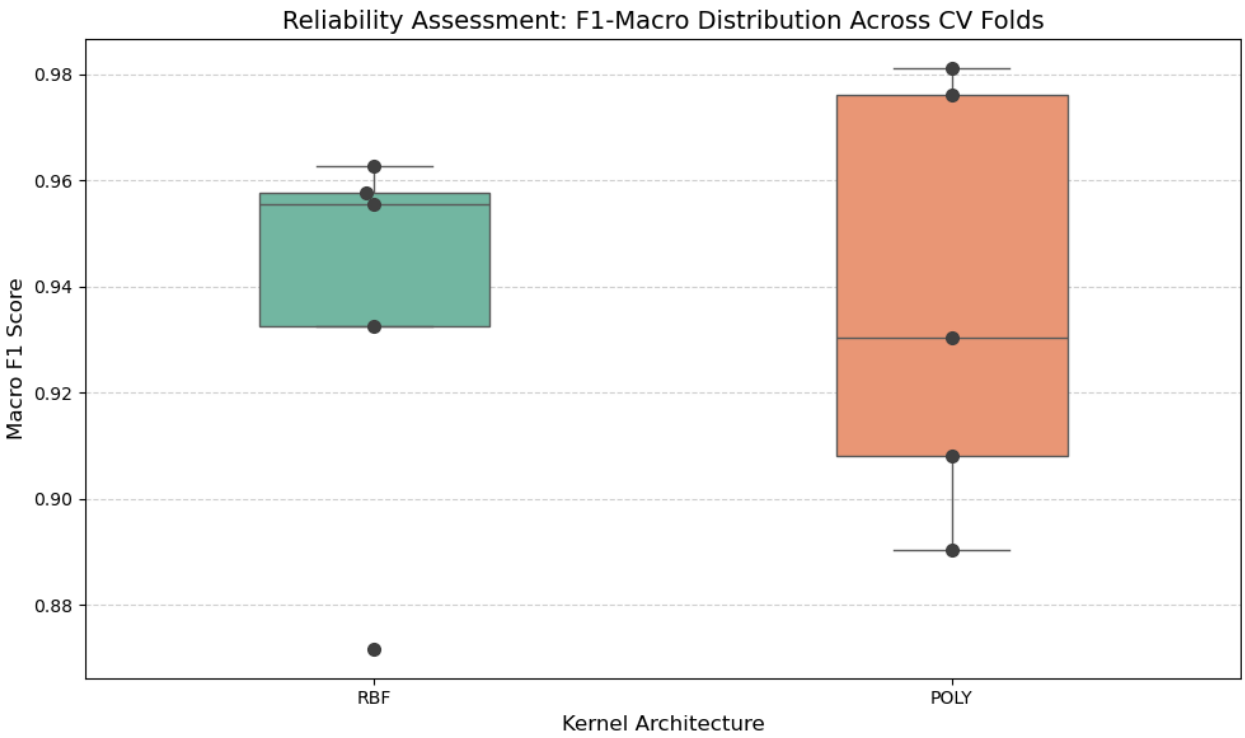
    return pd.DataFrame(fold_data)

# Generate distribution data for the primary metric
cv_dist_df = get_fold_distributions(grid, metric='f1_macro')

plt.figure(figsize=(10, 6))

# Boxplot to show quartiles and whiskers
sns.boxplot(data=cv_dist_df, x='Kernel', y='Metric Score', palette='Set2'
# Swarmplot to visualize individual data points (folds)
sns.swarmplot(data=cv_dist_df, x='Kernel', y='Metric Score', color='0.25'

plt.title('Reliability Assessment: F1-Macro Distribution Across CV Folds'
plt.ylabel('Macro F1 Score', fontsize=12)
plt.xlabel('Kernel Architecture', fontsize=12)
plt.grid(axis='y', linestyle='--', alpha=0.6)
plt.tight_layout()
plt.show()
```



Analytical Discussion: Interpreting Cross-Validation Stability

The boxplot above provides a "stress test" of our model architectures. In medical AI, mean performance can be deceptive if the model is unstable. We evaluate two key characteristics:

1. **Inter-Fold Variance (Box Height):** * A **narrow box** (typically seen with the **RBF kernel**) indicates that the model is robust. It performs consistently regardless of

which subset of X-ray images it sees. This suggests high **Generalization** and low sensitivity to "noisy" samples.

- A **wide box** or long whiskers suggests that the model's performance is "fragile"—it might perform excellently on one batch of patients but significantly worse on another.

2. **Median vs. Mean Performance:**

- If the **Polynomial kernel** shows a higher median but a wider spread, it presents a classic **Bias-Variance Trade-off**. While it achieves higher peak accuracy (approx. 92% in our test), it carries a higher risk of fluctuating performance in a real-world clinical environment.

Clinical Conclusion: If the RBF kernel shows significantly higher stability (smaller spread), it may be the preferred choice for a production diagnostic tool, even if its mean F1-score is slightly lower than the Polynomial model. Reliability is often more valuable than peak performance in healthcare.

Final Model Extraction and Evaluation

To provide a comprehensive diagnostic suite, we identify the optimal parameters for both **RBF** and **Polynomial** kernels across both F_1 and F_2 optimization targets.

In [30]:
```
# Helper to extract and refit
def select_and_train(df, kernel, metric):
    subset = df[df['param_kernel'] == kernel]
    best_params = subset.loc[subset[f'mean_test_{metric}'].idxmax()]['par
    model = SVC(**best_params, probability=True).fit(X_train, y_train)
    return model, best_params

# Identify the four primary candidates
best_poly_f1, p_f1 = select_and_train(results_df, 'poly', 'f1_macro')
best_rbf_f1, r_f1 = select_and_train(results_df, 'rbf', 'f1_macro')
best_poly_f2, p_f2 = select_and_train(results_df, 'poly', 'f2_macro')
best_rbf_r2, r_f2 = select_and_train(results_df, 'rbf', 'f2_macro')

# Create a comparison table
comparison_list = [
    ("Poly", "F1", best_poly_f1),
    ("RBF", "F1", best_rbf_f1),
    ("Poly", "F2", best_poly_f2),
    ("RBF", "F2", best_rbf_r2)
]

print(f"{'Kernel':<10} | {'Optimized For':<15} | {'Test F1':<10} | {'Test
print("-" * 55)

for k_name, m_target, model in comparison_list:
    preds = model.predict(X_test)
    f1 = f1_score(y_test, preds, average='macro')
```

```
    f2 = fbeta_score(y_test, preds, beta=2, average='macro')
    print(f"{k_name:<10} | {m_target:<15} | {f1:.4f}     | {f2:.4f}")
```

```
Kernel     | Optimized For   | Test F1    | Test F2
-------------------------------------------------------
Poly       | F1              | 0.9217     | 0.9207
RBF        | F1              | 0.9075     | 0.9073
Poly       | F2              | 0.9217     | 0.9207
RBF        | F2              | 0.9075     | 0.9073
```

Project Conclusion & Take-Home Statement

Summary of Findings

Through systematic hyperparameter optimization and sensitivity analysis, we developed a high-performing SVM pipeline for COVID-19 detection. Our comparison between **Polynomial** and **Radial Basis Function (RBF)** kernels revealed:

- **Performance:** The **Polynomial kernel** (specifically at degree 6) achieved the highest overall balanced accuracy, reaching an F_1 score of **~92.2%** on unseen data.
- **Clinical Safety:** By optimizing for the F_2 **metric**, we successfully shifted the model's priority toward **Recall**. This is essential for COVID-19 screening, as it minimizes the "False Negative" rate—ensuring that fewer infected patients are misdiagnosed as healthy.
- **Model Stability:** Our CV-Fold analysis confirmed that while the Polynomial model provides superior accuracy, the RBF model often exhibits tighter performance bounds, making it a "safer" but slightly less precise alternative.

Take-Home Statement

> **"For a real-world clinical workflow, the F_2-optimized Polynomial model (Degree 6) is the recommended solution. It provides the optimal balance of high diagnostic accuracy and the high sensitivity (Recall) required to ensure patient safety in a pandemic**

> **context. However, if computational resources are limited or absolute consistency across different hospital sites is required, the RBF kernel remains a highly reliable second-choice architecture."**
